More patients in need organ transplant than organs available → In 2015, 122,071 waiting at year end, 30,975 transplants performed, and 15,068 donors recovered

United Network for Organ Sharing (UNOS) responsible for orderly offering deceased donor organs

Order in which deceased donor organs offered to recipients a deterministic function (urgency, benefit, geography, organ quality, fairness)
Donor Lung Offers in the United States

Lung Allocation in the United States. Left figure from Colvin-Adams (2012)
Organ Acceptance

- Each time an organ is offered to a recipient it may be turned down
- Many competing factors go into organ acceptance
  1. Patient
  2. Surgeon
  3. Transplant Center
  4. Organ Procurement Organization
  5. Other Patients on Waiting List
Patients awaiting organ transplantation face a difficult decision if offered a low-quality organ:
  ▶ Accept the organ
  ▶ Decline the organ, hope to be offered a higher quality one in the future

Testing the effect of personalized decision rules (dynamic transplant regimes) would be helpful here.
Treatment regimes of interest: Rules which dictate when an offered organ should be declined

Treatment regimes for transplantation tend to be “poorly-defined”:

- There is not a 1-to-1 correspondence between patient covariate history and treatment
- Transplants are not available at any time
- We cannot easily specify treatment regimes such as “Get a transplant as soon as LAS > 50” because these regimes are not clinically meaningful
- Avoid regimes which dictate if an organ should be accepted
No randomized trials of different transplant regimes
Necessitates the use observational datasets and appropriate methods
Inverse probability of compliance estimators →

1. Patient’s follow-up time is considered only while she is “compliant” with a regime of interest
2. Once non-compliant, her follow-up time is artificially censored
3. Observations are weighted according to the inverse of probability of compliance to correct for the potential selection bias introduced by the artificial censoring
Limitations of Existing Methods

Problem:

- Anticipated survival for a given DTR depends on the quality and availability of organs, and these depend on the strategies that other patients follow to accept or decline an organ
- Patients’ probability of transplant depends on regimes that other patients follow
- Conceptually similar, although not identical, to the “spillover” effect described in other contexts

Existing methods have a major limitation here:

- They estimate the causal effect of a treatment regime for a single random participant who adopts the treatment regime
- But the causal effect if all patients were to adopt the treatment regime may have more public health relevance
Develop weighted causal estimators for both cases:

- “One follows”
- “All follow”

Develop estimators:

- Assuming we have data from an observational registry
- Avoid modeling the many random processes: patient arrival, organ arrival, etc...
Potential Outcomes and Target of Interest

- \( T^*(\infty) \): survival time from listing if the patient were to never receive a transplanted organ
- \( T^*(b, q) \): survival time if the patient were to receive an organ \( b \) days after listing with organ characteristics \( q \)
- \( \mathbf{X}^*(b) \) to be the covariates collected \( b \) days after listing
- Inferring the distribution of \( T^*(b, q) \) is not of primary interest
- \( T^*(g, g') \): survival time if she followed regime \( g \) for declining offered organs and all other patients follow regime \( g' \)
- Inferring the distribution of \( T^*(g, g') \) IS of primary interest
Potential Outcomes and Target of Interest

- Density of $T^*(g, g')$ ($f_{T^*}(g, g')(t)$) is a mixture distribution of well-defined counterfactual survival times

$$
\sum_{t|\overline{x}(t)} f_{T^*(\infty)|\overline{x}^*(t)} \left[ \prod_{s=1}^{t} 1 - \sum_{q} \rho^{(g, g')} \{s, q|\overline{x}(s)\} \right] f_{\overline{x}^*(t)} \{\overline{x}(t)\} \\
+ \sum_{b=1}^{t} \sum_{q} \sum_{\overline{x}(b)} f_{T^*(b, q)|\overline{x}^*(b)} \left[ \prod_{s=1}^{b-1} 1 - \sum_{q} \rho^{(g, g')} \{s, q|\overline{x}(s)\} \right] \rho^{(g, g')} \{b, q|\overline{x}(b)\} f_{\overline{x}^*(b)} \{\overline{x}(b)\},
$$

- $\rho^{(g, g')} \{b, q|\overline{x}(b)\}$: probability of receiving a transplant $b$ days after listing with organ characteristics $q$ given she is untransplanted $b - 1$ days after listing with covariate history $\overline{x}(b)$ and the patient follows regime $g$ while all others follow regime $g'$
“Spillover” typically refers to situations in which the distribution of well-defined potential outcomes depends on the treatment assignment of others.

Here the probability of initiating treatment depends on the treatment regime other patients follow.

Refer to this as transplant regime spillover.
Notation:

- $L_i$: listing time for $i$th patient
- $N_{ij}, Y_{ij}$: failure and at-risk indicators for $i$th patient on $j$th study day
- $X_{ij}$: patient characteristics including confounders
- $A_{ijk}$: indicator for accepting $k$th organ on the $j$th study day
- $\bar{A}_{ij}$: treatment history through the $j$th day
- $O_{ijk}$: indicator for offered $k$th organ on $j$th study
- $\bar{E}_{jk}$ to be the collection of information on all subjects prior to assigning the $k$th organ on the $j$th study day

Causal estimand: $\lambda_t(g, g')$: hazard of death $t$ days after entering the waiting list, and the associated survival $S_t(g, g')$
Components of the weights

\[ \pi_{ij}^{(\emptyset, \emptyset)} (\overline{A}_{ij}, \overline{E} \cdot jS_j) = \prod_{j' = 1}^{j} \prod_{k = 1}^{S_{j'}} \pi_{ijk}^{(\emptyset, \emptyset)} (A_{ij'k}, E_{j'k}) : \text{The probability of the observed treatment history assuming all patients follow regime } \emptyset \text{ (no changes in propensity to accept or decline organs)} \]

\[ \pi_{ij}^{(g, g')} (\overline{A}_{ij}, \overline{E} \cdot jS_j) = \prod_{j' = 1}^{j} \prod_{k = 1}^{S_{j'}} \pi_{ijk}^{(g, g')} (A_{ij'k}, E_{j'k}) : \text{The probability of the observed treatment history in the counterfactual world where } i\text{th patient follows regime } g \text{ and all others follow } g' \]
We can estimate $\lambda_t(g, g')$ by solving the estimating equation:

$$\sum_{j=1}^{m} \sum_{i=1}^{n} \frac{\pi_{ij}^{(g,g')}(A_{ij}, \overline{E} \cdot jS_j)}{\pi_{ij}^{(\emptyset,\emptyset)}(A_{ij}, \overline{E} \cdot jS_j)} \left\{ N_{ij} - Y_{ij} \lambda_t(g, g') \right\} I(j - L_i = t) = 0$$

Intuition for the weights:

- Similar to IPCW
- Standardize to the target population where probability of $A_{ij}$ is different
- Mean zero estimating function $\rightarrow$ estimator for $\lambda_t(g, g')$ is CAN
Estimating $\pi_{ij}^{(\emptyset,\emptyset)}(\overline{A}_{ij}, \overline{E}_{jS_j})$ with the Observed Data

$\pi_{ij}^{(\emptyset,\emptyset)}(\overline{A}_{ij}, \overline{E}_{jS_j})$ is a function of the probability of being offered, and the probability of accepting if offered:

- $\Pr(A_{ij} = 1) = \Pr(O_{ij} = 1) \cdot \Pr(A_{ij} = 1|O_{ij} = 1)$
- $\Pr(A_{ij} = 0) = 1 - \Pr(O_{ij} = 1) \cdot \Pr(A_{ij} = 1|O_{ij} = 1)$

Estimating $\Pr(O = 1)$ is straightforward provided I have a model for $\Pr(A = 1|O = 1)$
Estimating $\pi_{ij}^{(0,0)} (\overline{A}_{ij}, \overline{E}_{jS_j})$ with the Observed Data

| ID  | LAS  | A | Pr($A = 1| O = 1$) | Pr($O = 1$) | Pr($A$) |
|-----|------|---|-------------------|-------------|---------|
| 763 | 52.54| 0 | 0.563             | 1.000       | 0.437   |
| 197 | 43.33| 1 | 0.339             | 0.437       | 0.148   |
| 553 | 41.60| 0 | 0.302             | 0.289       | 0.913   |
| 66  | 33.38| 0 | 0.160             | 0.202       | 0.968   |
| 592 | 33.31| 0 | 0.158             | 0.169       | 0.973   |
Estimating $\frac{\pi (g, g')}{\pi (g, g')}$ ($\overline{A}_{ij}$, $\overline{E}_{jS_j}$) with the Observed Data

This is more challenging.

The numerator is the expectation of the probability of being offered and accepting organs in the hypothetical world where all patients follow regime $g'$ given the observed data.

$$\pi_{ijk} (1, E_{jk}) = E (\pi_{ijk} (1, E_{jk}) | E_{jk})$$

If all patients follow regime $g'$:

- We don’t know which patients would be on the waiting list
- We don’t know what their characteristics would be
- The probability of being offered an organ can’t be directly computed from the observed data
- Sample $E_{jk}^{(g, g')}$ from $E_{jk}$ – use Monte Carlo integration to evaluate expectation
Estimating $\pi_{ij}^{(g,g')} (\overline{A}_{ij}, \overline{E}_{jS})$

| ID  | LAS  | A  | $\Pr(A = 1| O = 1)$ | $\Pr(O = 1)$ | $\Pr(A)$ |
|-----|------|----|---------------------|---------------|----------|
| 763 | 52.54| 0  | 0.563               | 1.000         | 0.437    |
| 761 | ?    | ?  | ?                   | 0.437         | ?        |
| 197 | 43.33| 1  | 0.339               | ?             | ?        |
| 491 | ?    | ?  | ?                   | ?             | ?        |
| 553 | 41.60| 0  | 0.302               | ?             | ?        |
| 66  | 33.38| 0  | 0.160               | ?             | ?        |
| 592 | 33.31| 0  | 0.158               | ?             | ?        |
Estimating $\pi_{ij}^{(g,g')} (\overline{A}_{ij}, \overline{E}_{jS_j})$

Hot Deck Imputation:

- For all transplant recipients, impute missing data assuming never transplanted by borrowing data from their nearest neighbor, the “lender”
- Simulate the organ allocation when everyone follows $g'$, assuming model for accepting organs holds
- Assume low quality organs are accepted with probability 0

We’ve created a hypothetical data set where all patients follow $g'$. 
After Imputation

Assume the organ is defined as high quality under $g'$

| ID  | LAS   | A  | Pr($A = 1|O = 1$) | Pr($O = 1$) | Pr($A$) |
|-----|-------|----|-------------------|-------------|---------|
| 763 | 52.54 | 0  | 0.563             | 1.000       | 0.437   |
| 761 | 49.48 | 0  | 0.367             | 0.437       | 0.840   |
| 197 | 43.33 | 1  | 0.339             | 0.277       | 0.094   |
| 491 | 42.55 | 0  | 0.237             | 0.183       | 0.957   |
| 553 | 41.60 | 0  | 0.302             | 0.140       | 0.958   |
| 66  | 33.38 | 0  | 0.160             | 0.097       | 0.984   |
| 592 | 33.31 | 0  | 0.158             | 0.082       | 0.987   |
After Assigning Organ Under $g, g'$

Assume the organ is defined as high quality under $g'$

Simulation Study

Data Generation:

- Patient and organ arrivals: independent Poisson processes with rate parameters 0.5 and 0.32, respectively

- \( b_{i0} \sim N(-1, 1), \ b_{i1} \sim N\left(\frac{1}{365}, \frac{1}{(4 \cdot 365)^2}\right) \)

- \( X_{ij} = b_{i0} + b_{i1} \cdot \lfloor \frac{j-L_i}{30} \rfloor \cdot 30 \), where \( \lfloor \cdot \rfloor \) is the floor function, \( L_i \) is arrival time

- Organs were low-quality with probability 0.5

- Organs were accepted with probability \( \left\{1 + e^{2.5 - 0.25X_{ij}}\right\}^{-1} \)
Simulation Study

Estimation:

- Estimated survival for regime $g$: decline all low-quality organs
- Estimated survival assuming “one follows” and “all follow”
- Hot deck imputation: lender $i'$ for patient $i$ selected as $\arg \min_{i'} \left( |X_{ij} - X_{i'j'}| : j - L_i = j' - L_{i'} \right)$
- Nonparametric bootstrap to estimate standard errors (SEs) and form 95% confidence intervals (CI)

Application

Data are from an observational registry maintained by the United Network for Organ Sharing

- May 4, 2005-Sept 30, 2011
- 9,091 transplants
- 13,039 patients total

Treatment regimes:
- Decline organs below $p$th percentile of donor quality while \( \text{LAS} < M \); if \( \text{LAS} \geq M \), any organ is acceptable
- $p$ and $M$ can both vary
- Estimated anticipated survival assuming “one follows” the regime, or “all follow” the regime.
Donor quality:
▶ Donor quality modeled with Cox regression
▶ For each transplant, donor quality was estimated for each potential recipient

Model for accepting organs:
▶ Logistic regression model
▶ Predictors: patient age, LAS, time on waiting list, native disease, patient-donor-height difference; and indicators for donor smoking \( \geq 20 \) pack-years, donor age \( > 50 \), and their interaction
Hot deck imputation for “all follow”:

- Lender $i'$ for patient $i$ selected as
  \[
  \arg \min_{i'} (|\text{LAS}_{ij} - \text{LAS}_{i'j'}| : j - L_i = j' - L_{i'})
  \]

- \text{LAS} was only imputed variable

Nonparametric bootstrap to estimate SEs and form 95% CIs
Decline All Organs Until LAS Exceeds 40 Years From Entering Waitlist

Cumulative Probability of Death

Kaplan–Meier Survival

- - - One Participant Follows Regime

- - - All Participants Follow Regime

Years From Entering Waitlist
Application Results

All Follow Regime 'Decline All Organs Until LAS Exceeds Cutoff'

Cumulative Probability of Death

Kaplan–Meier Survival

- LAS Cutoff = 35
- LAS Cutoff = 40
- LAS Cutoff = 45
- LAS Cutoff = 50

Years From Entering Waitlist

0.0 0.1 0.2 0.3 0.4
0 1 2 3
One Follows Regime 'Decline Worst $p\%$ of Organs Until LAS Exceeds 50'

Years From Entering Waitlist
Cumulative Probability of Death
Kaplan−Meier Survival

- $p = 25$
- $p = 50$
- $p = 75$
- $p = 100$
Summary

Simulation shows:
  ▶ Estimators have little bias for their target
  ▶ Causal estimand must be specified with care

Application
  ▶ “One follows” and “all follows” are different
  ▶ Patients may gain a modest increase in survival probability by declining transplantation while $LAS$ is low
  ▶ Effect may be greater if the entire population adopts the strategy
Thank you!
